

1.12 Game Trees: Extensive Form

To completely specify a game, we need to know:

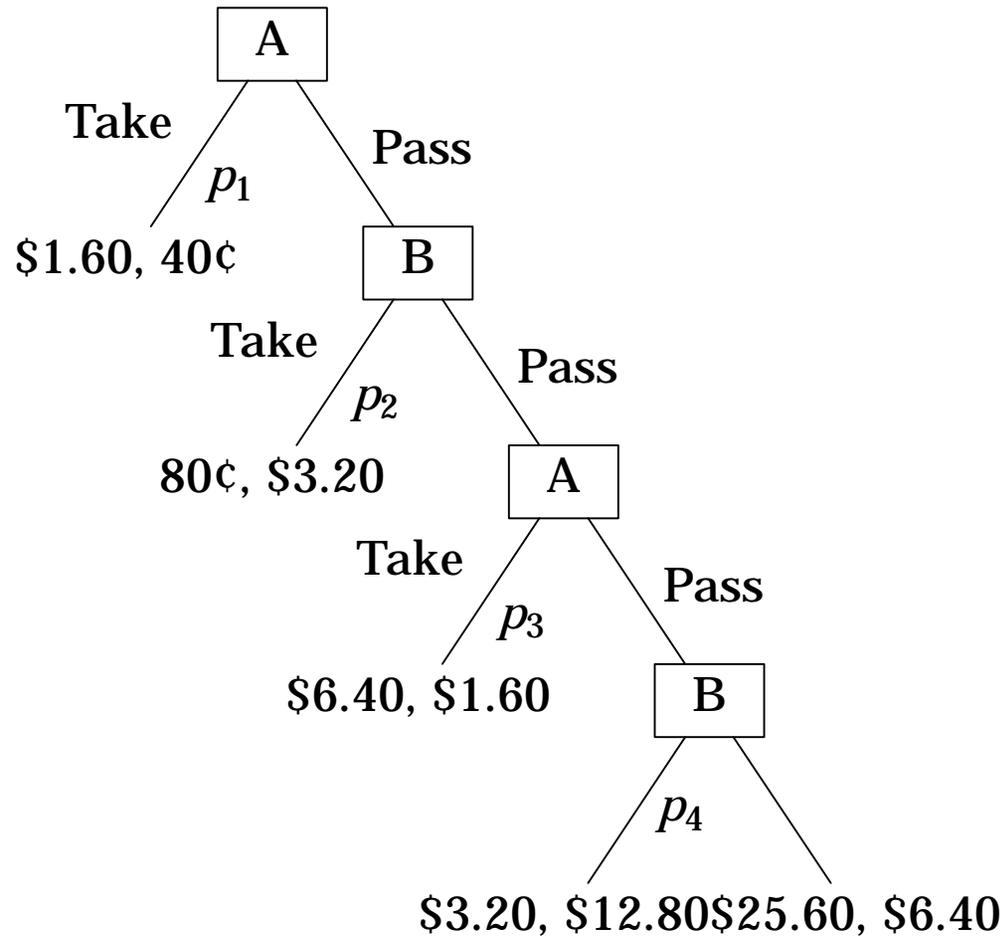

- *the set of players* (who)
- the set of situations (nodes) and the sequence of their appearance, i.e., *the game tree*
- who moves at each decision node, i.e., *the player partition* (order of play , i.e., sequential)
- which decision nodes each player can distinguish i.e., *the information partition* (who knows what when)
- what choices each player has at each information set (choice of actions)
- what the payoffs to the players are whenever the game ends, i.e., *the payoff function* (who gets what when)

Games in which each player knows exactly what has happened in previous moves are called *games with perfect information*. Otherwise they are *games with imperfect information*. This is a structural property of the game.

1.12.1 Centipede Game 1

1.12.2 Centipede Game 2

1.13 Common Knowledge

Common knowledge = complete information

An example from Halpern:

- Three divisions camped on two hilltops overlooking a valley, where awaits the enemy.
- if all three divisions attack the enemy simultaneously, they will win a battle, whereas
- if only one or two divisions attack, they will be defeated.
- no prior plans for launching an attack on the enemy
- but General Able of the 1st division wishes to coordinate with Generals Baker and Charlie of the 2nd and 3rd a simultaneous attack (at some time the next day).
- None will attack unless sure that the others will both attack with him.
- can only communicate by means of a messenger.
- one hour to get between Able and Baker and Charlie
- possible that he will get lost in the dark or be captured by the enemy.
- Question: How long will it take them to coordinate an attack?

Suppose the messenger sent by General Able makes it to General Baker and then to General Charlie with a message saying, “Let’s attack at dawn.” Will Baker attack?

Of course not, since Able does not know that Baker and Charlie have received the message, and thus may not attack.

So Baker sends the messenger to Charlie and Able with an acknowledgement. (Why both?) Suppose the messenger makes it. Will Able attack?

No, because now Baker does not know that Able got the message, so Baker thinks that Able may think that Baker didn’t get the original message, and thus not attack. Likewise for Charlie.

So Able sends the messenger back with an acknowledgement. But of course this is not enough either.

So: How many acknowledgements, suitably acknowledged, are necessary for Able and Baker to know with absolute certainty that the other divisions will attack at dawn?

No number of acknowledgements sent back and forth ever guarantees agreement.

A lack of Common Knowledge

There is a lack of *common knowledge* about the schedule. This is a case of *incomplete information*.

In practice, most generals would act without perfect information, perhaps after Able had received Baker's and Charlie's first acknowledgement?

Michael Chwe's book *Rational Ritual: Culture, Coordination, and Common Knowledge*, (P.U.P., 2001) uses two people at each end of a crowded bus as an example.

He also argues that public ritual is a way of achieving common knowledge.

Modern technology allows choice of common knowledge or not:

- Using Bcc: (blind carbon copy) when sending out email invitations can be counterproductive: recipients lack common knowledge of the names of the other invitees — perhaps the party will not be as successful as if the Cc: field had been used.
- To talk (→ common knowledge) or to SMS — that is the question!

1.14 Definitions — Rasmusen

- The **players** are the individuals who make decisions. Each *player's goal* is to maximise his utility by choice of actions.
- **Nature** is a non-player who takes random actions at specified points in the game with specified probabilities.
- An **action** or *move* by player i is a choice he can make.
- Player i 's **action set** is the entire set of actions available to him.
- An **action combination** is an ordered set of one action for each of the n players in the game.
- The **players' order of play** must be specified.
- Player i 's **strategy** s_i is a rule that tells him which action to choose at each instant of the game, given his information set.
- Player i 's **strategy set** or *strategy space* is the set of strategies or rules available to him.
- A **strategy combination** is an ordered set consisting of one strategy for each of the n players in the game.

- By player i 's **payoff** we mean either:
 1. The utility he receives after all players and Nature have picked their strategies and the game has been played out; or
 2. The expected utility he receives as a function of the strategies chosen by himself and the other players.
- The **outcome** of the game is a set of interesting elements that the modeller picks out from the values of actions, payoffs, and other variables after game is played out.
- An **equilibrium** is a strategy combination consisting of a best strategy for each of the n players in the game.
- An **equilibrium concept** or *solution concept* is a rule that defines an equilibrium based on the possible strategy combinations and the payoff functions.
- Player i 's **best response** or *best reply* to the strategies chosen by the other players is the strategy s_i^* that yields him the greatest payoff.
- The strategy s_i^* is a **dominant strategy** if it is a player's strictly best response to **any** strategies the other players might pick, in the sense that whatever strategies they pick, his payoff is highest with s_i^* .

- His inferior strategies are **dominated strategies**.
- A **dominant strategy equilibrium** is a strategy combination consisting of each player's dominant strategy.
- A **cooperative game** is a game in which the players can make binding commitments, as opposed to a **non-cooperative game**, in which they cannot.
- Cooperative games often allow players to split the gains from cooperation by making **side-payments**—transfers among themselves that change the prescribed payoffs (promises or threats in a non-cooperative game).
- Strategy s_i^* is a **weakly dominant strategy** if it is a player's best response to any strategies the other player might pick, in the sense that whatever strategies they pick, his payoff is no smaller with s_i than with any other strategy, and is greater in some strategy combination.
- An **iterated dominant strategy equilibrium** is a strategy combination found by deleting a weakly dominated strategy from the strategy set of one of the players, recalculating to find which remaining strategies are weakly dominated, deleting one of them, and continuing the process until only one strategy remains for each player.

- A **zero-sum game** (or constant-sum game) is a game in which the sum of the payoffs of all the players is zero (or constant) whatever they choose.
- The strategy combination s^* is a **Nash equilibrium** if no player has incentive to deviate from his strategy given that the other players do not deviate.
- A **subgame** is a game consisting of a node which is a singleton in every player's information partition, that node's successors, and the payoffs at the associated end nodes.
- A strategy profile is a **subgame perfect Nash equilibrium** if (a) it is a Nash equilibrium for the entire game; and (b) its relevant action rules are a Nash equilibrium for every subgame.

The term **sequential rationality**: the idea that a player should maximise his payoffs at each point in the game, re-optimising his decisions at each point and taking into account the fact that he will re-optimize in the future.

A blend of the economic ideas of rational expectations and ignoring sunk costs.

Sequential rationality has great power.

(See Chapter 4 of Rasmusen: 4.3 Nuisance Suits.)

- The outcome O of a game is **Pareto dominated** if there is some other outcome O' such that:
 1. every player either strictly prefers O' to O or is indifferent between O' or O , *and*
 2. some player strictly prefers O' to O .
- An outcome is **Pareto optimal** or **Pareto efficient** if it is not Pareto dominated by any other outcome of the game.

(Bierman & Fernandez, 2nd ed., p.10)

In zero-sum games ...

1.15 Oligopolies: Continuous Strategies

1.15.1 A Von Stackelberg Leader-Follower Model.

e.g., duopoly — two sellers — **von Stackelberg** model describes a dominant firm (once IBM, now Microsoft, or OPEC, etc.)

Model:

- Leader (Spring) produces quantity Q_S of bottled water, and
- Follower (Crystal) produces Q_C of identical water.
- market demand → price P (equal for both)
$$P = 10 - (Q_S + Q_C), \quad Q_S + Q_C \leq 10.$$
- common knowledge: Spring sets its production level before Crystal does
- each firm's production level: common knowledge
- order of play & output choices: common knowledge
- no capacity constraints

Let's put numbers in:

- each firm has identical costs ($i = C, S$):

$$MC_i = AC_i = \$3/\text{unit}$$

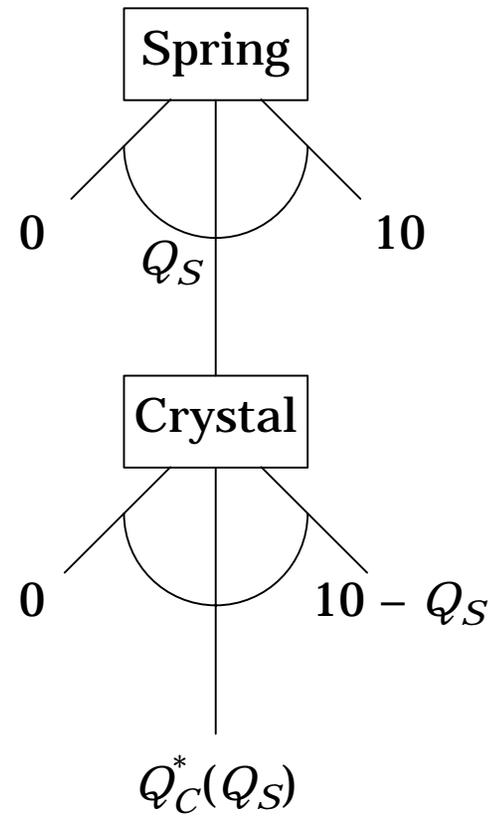

- ∴ payoffs for either firm i are ($i = C, S$):

$$\pi_i(Q_S, Q_C) = (10 - Q_S - Q_C)Q_i - 3Q_i$$

- zero output → zero profit

Questions:

- What should the Leader (Spring) do?
Depends on how the Leader thinks the Follower (Crystal) will react.
Spring should: *Look forward and reason back.*
- for every fixed level of output for Spring, what is the best (profit-maximising) level that Crystal can do? What is the Follower's *reaction function*?

Cournot Rivalry Game Tree

(Quant. \Rightarrow Cournot,
Price \Rightarrow Bertrand.)

- Crystal (the Follower): chooses Q_C^* to max his profit:

$$\pi_C = P(Q_S + Q_C) Q_C - TC_C(Q_C)$$

$$\pi_C = (10 - (Q_S + Q_C)) Q_C - 3 Q_C$$

- From Crystal's viewpoint, Spring's (the Leader's) output is predetermined — a constant Q_S , because Spring will have moved first,

so Crystal sets $MR_C(Q_S, Q_C) = MC(Q_C) = 3$ to get Q_C^* :

$$MR_C(Q_S, Q_C^*) = (10 - Q_S - Q_C^*) + \frac{\partial P}{\partial Q_C} Q_C^* = 3$$

$$\rightarrow Q_C^* = f_C(Q_S),$$

the profit-maximising output Q_C^* of Follower (Crystal) is a function of the Leader's choice Q_S

- This function is known as the *reaction function*, since it tells us how the Follower will react to the Leader's choice (of output in this case).
- It is the locus of points where the family of Crystal's isoprofit curves have zero slope, w.r.t output Q_C . Why?

- Solving for Q_C^* :

$$Q_C^* = \frac{7 - Q_S}{2}$$

Crystal's *reaction function*, contingent on Spring's action Q_S

- Looking forward & reasoning back, Spring knows this, so Spring's profit:

$$\pi_S = (10 - (Q_S + \frac{7 - Q_S}{2})) Q_S - 3Q_S$$

Solving for maximum π_S ($d\pi/dQ_S = 0$) gives:

π_S max when $Q_S^* = 3.5$,

with $\pi_S^* = \$6.125$ and $P = \$4.75$

and $Q_C^* = 1.75$ and $\pi_C^* = \$3.06$

- So Spring's *first-mover advantage* is

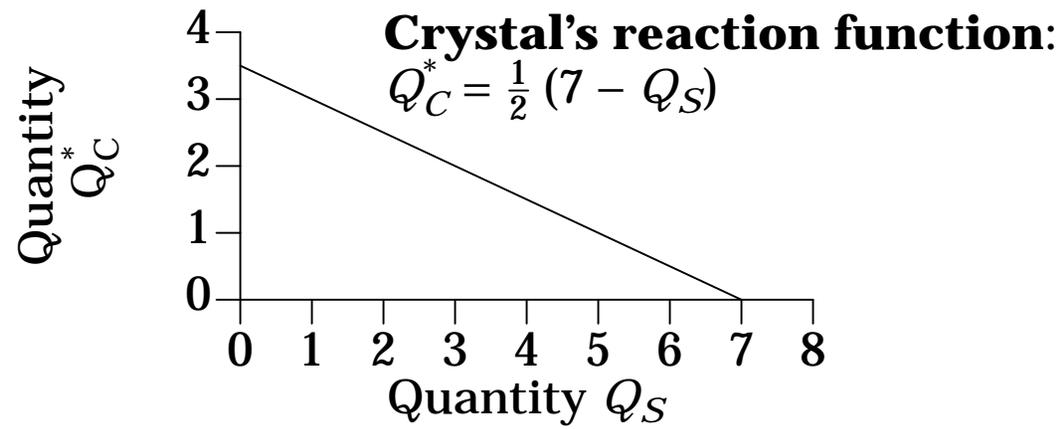

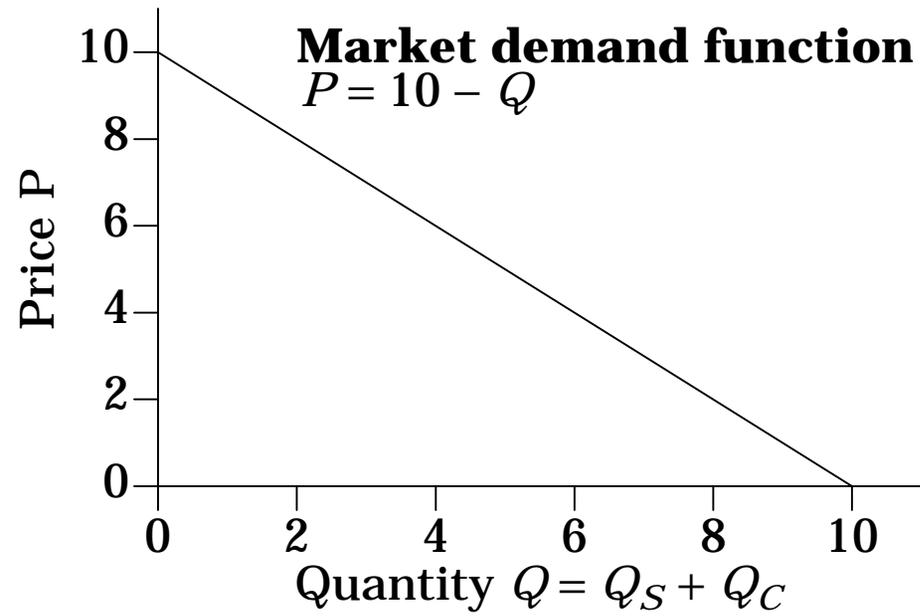

$$\$6.125 - \$3.06 = \$3.06$$

- leadership — first mover
- leadership — innovator, monopolist, faced with threat of entry
- incumbent erects barriers to entry by new-comer
- long-term contracts reduce incumbent's flexibility and increase the credibility of defence
- The monopolist quantity in this case is

$$Q_M = 3.5, \text{ with } P_M = \$6.5$$

$$\text{and profit } \pi_M = 6.5 \times 3.5 - 3 \times 3.5 = \$12.25$$

This means that the Leader could pay the Follower not to enter the market by offering him his (Follower's) profit of \$3.06 not to, and still be ahead by $\$12.25 - 3.06 - 6.125 = \3.06 .

1.15.2 Simultaneous Cournot.

How much will each firm produce if they move simultaneously?

Each needs to:

1. make a *conjecture about how much the other firm will produce* — will it be high, with a lower industry price? Or vice versa?
2. then determine *its own quantity to produce* — balancing the gain from selling more units against the cost of a lower price.

Industry-wide equilibrium when both firms resolve this balance.

From Spring's point of view, what should Q_S be?

- If Crystal produces Q_C , then I, Spring, should max my profit π_S :

$$\pi_S = (10 - Q_C - Q_S) Q_S - 3Q_S$$

- which is maximised at

$$Q_S^* = \frac{1}{2} (10 - 3 - Q_C) = \frac{1}{2} (7 - Q_C)$$

This is Spring's *best response* to Crystal's quantity choice of Q_C , or $R_S(Q_C)$.

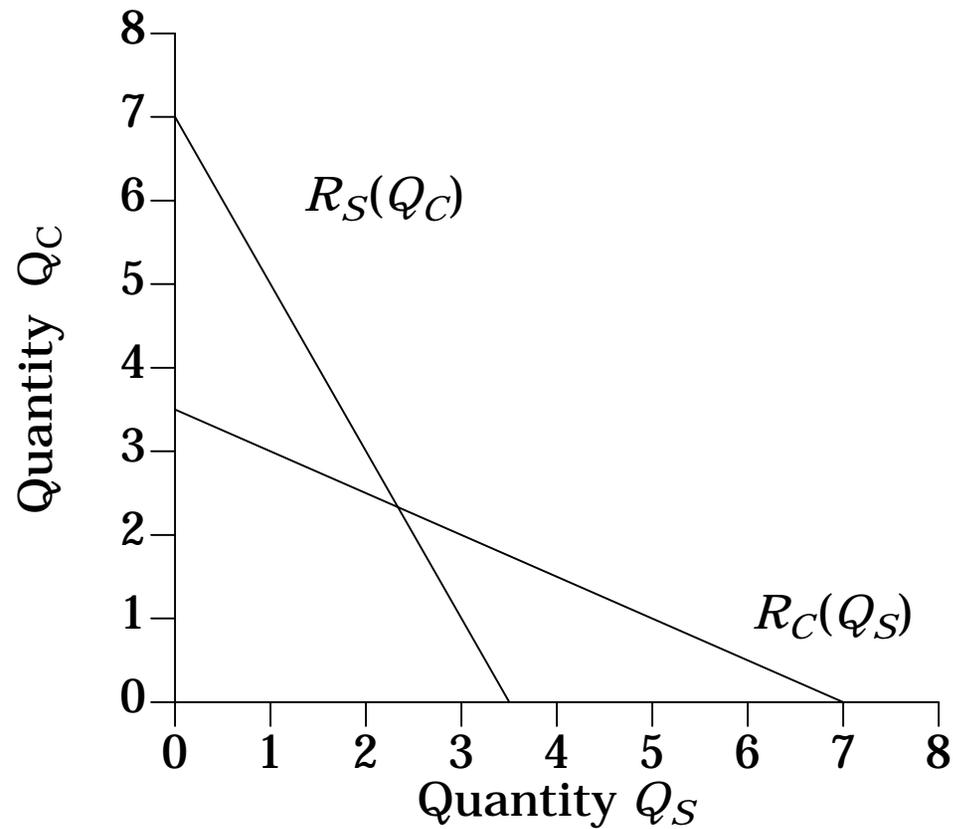

- If Q_C exceeds 7 units, then Spring should produce zero.

Symmetrically, Crystal's *best response* $R_C(Q_S)$ to a conjectured production level of Q_S from Spring should be:

$$Q_C^* = \frac{1}{2} (7 - Q_S)$$

Reaction Functions:

Plotting both best responses, or *reaction functions*:

The Two Best-Response Curves: Cournot

Equilibrium.

There is a unique pair of quantities at which the two reaction functions cross:
 (Q_S^*, Q_C^*) .

Hence at this point:

$$R_C(Q_S^*) = Q_C^* = 2\frac{1}{3} \text{ and}$$
$$R_S(Q_C^*) = Q_S^* = 2\frac{1}{3}.$$

This is a so-called *Cournot Nash equilibrium*, where each player's conjecture is consistent with the other's actual production, and neither has any incentive to alter production.

Price/unit = $\$5\frac{1}{3}$, profit of each = \$5.44

1.15.3 Simultaneous Price (Bertrand) Competition, Imperfect Substitues.

Two pizzerias, Donna's Deep Dish and Perce's Pizza Pies, compete in a small town.

Suppose it costs \$6 to make each pizza, and experience has shown that when Donna's price is P_d and Perce's price is P_p their respective sales Q_d and Q_p (measured in hundreds of pizzas per week) are given by:

$$Q_d = 24 - P_d + \frac{1}{2} P_p$$
$$Q_p = 24 - P_p + \frac{1}{2} P_d$$

The two brands of pizza are (*imperfect*) *substitutes*: if the price of one rises, sales of the other go up: half the discouraged buyers switch to the other pizza and half move to some other kind of food (Big Macs?)

Perce will set his price P_p to maximise his profits:

$$\pi_p = (P_p - 6) Q_p = (P_p - 6) (24 - P_p + \frac{1}{2} P_d)$$

His best price P_p for each possible level of Donna's price P_d will give Perce's best response.

Multiply out the terms in Perce's profit function:

$$\pi_p = -144 - 3P_d + (30 + \frac{1}{2} P_d) P_p - P_p^2$$

Differentiating with respect to P_p (holding the other shop's price P_d constant):

$$\frac{d\pi_p}{dP_p} = 30 + \frac{1}{2} P_d - 2 P_p.$$

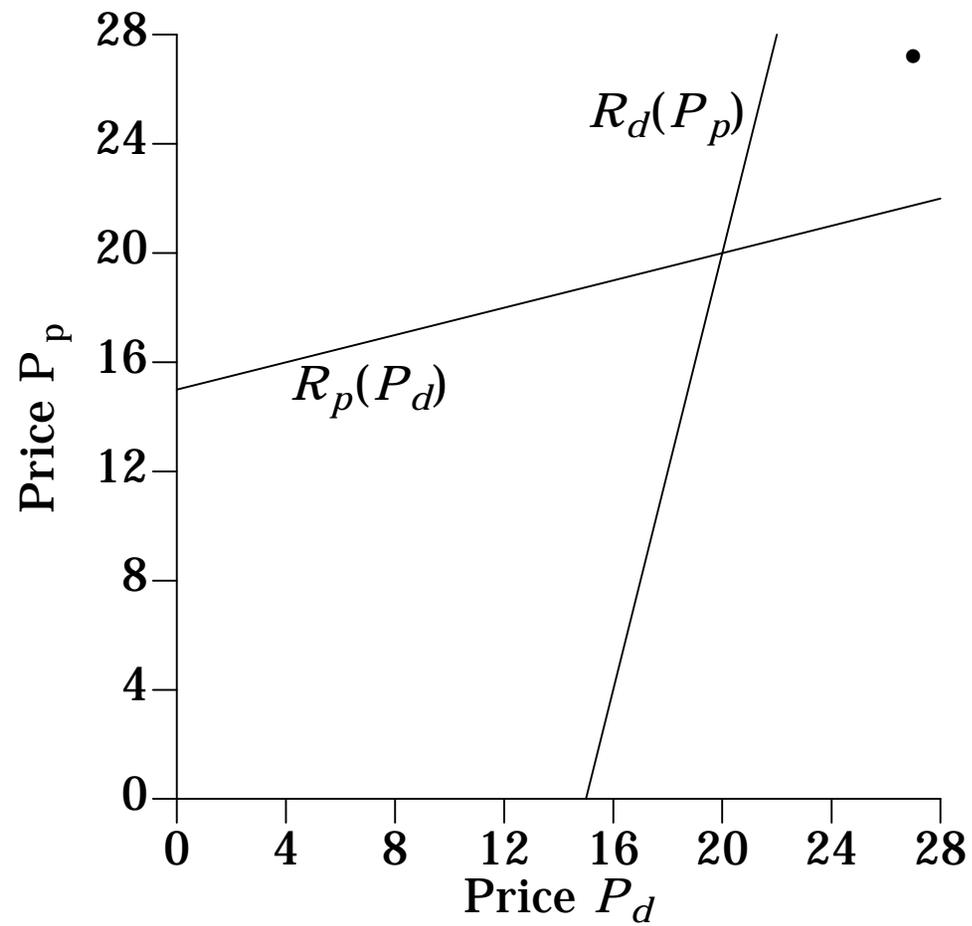

The first-order condition for P_p to max π_p is that this derivative should be zero, which gives the best-response curve $R_p(P_d)$ for Perce as:

$$P_p = 15 + \frac{1}{4} P_d$$

Symmetrically (in this example) Donna's best-response curve $R_d(P_p)$ is:

$$P_d = 15 + \frac{1}{4} P_p$$

So if Donna's price is \$32, then Perce's best response is \$23, and vice versa.

The Two Best-Response Curves: Bertrand

The two curves intersect at the Nash Equilibrium of the shops' pricing game, at $P_d = P_p = \$20$.

At those prices, each shop sells 1400 pizzas a week, at a profit per shop of \$19,600 per week.

The best-response curves slope up, so when one shop raises its price by \$1, its rival should increase its price by 25¢: when the first shop raised its price, some of its customers switched to its rival, which could then best profit from the new customers by raising its price somewhat.

Thus a shop that increases its price is helping increase the profits of its rival, but this side-effect is uncaptured (and so ignored) by each shop independently.

But, as in the PD, they could collude and increase their profits: if they each charged, say, \$24, each would sell 1200 pizzas, for a profit of \$21,600.

But if $P_d = \$24$, then Perce's best response would be \$21, to which Donna would respond with \$20.25, etc., etc, until they converge to \$20.

What is best for them jointly?

Let $P_d = P_p = P$ (they both charge P) and π is maximised when $P = \$27$; at which price each sells 1050 pizzas, at a profit of \$22,050 per shop.

Which form of competition: Cournot (quantity) or Bertrand (price)?

Changing prices can be costly, but so can changing the flow of production to increase or cut back the quantity of good flowing to the market.

Cournot applies most naturally to markets in which firms must make production decisions in advance and face high costs for holding inventories: price will adjust more quickly than quantity, and each firm will set a price that sells all that it produces.

Such a firm will not expect to steal customers by lowering its price, since its rivals will immediately match any price change, so that their sales equal their planned production volumes. Hence less competition than Bertrand.

When firms choose capacity first, and then compete as price setters given the capacities chosen earlier, the result is identical to Cournot quantity competition.

When capacity is sufficiently flexible to allow them to adjust production to meet all the demand for their product at any price they announce, **Bertrand** price competition results. With perfect substitutes, firms will attempt to steal customers by price cutting down to marginal cost.

(See Besanko et al. Chapter 7: Market Structure and Competition.)

1.16 Strategic Complements and Strategic Substitutes

Compare the reaction functions in the Cournot (quantity) game between the water sellers and those in the Bertrand (price) game between the pizzerias.

In the Cournot model the reaction functions were downwards sloping and in the Bertrand model they were upwards sloping.

Strategic complements:

in general, when reaction functions are *upwards sloping* we say that the firms' actions (here, prices) are *strategic complements*.

Strategic substitutes:

in general, when reaction functions are *downwards sloping* we say that the firms' actions (here, quantities) are *strategic substitutes*.

Meaning?

When actions are *strategic complements*, the more of the action one firm chooses, the more of the action the other firm will optimally choose.

In the Bertrand (price) model, prices are strategic complements: a competitor's price cut will best be responded to by a price cut. → price wars.

When actions are *strategic substitutes*, the more of the action one firm chooses, the less of the action the other firm will optimally choose.

In the Cournot (quantity) model, quantities are strategic substitutes: a competitor's quantity increase will best be responded to by a quantity cut.

A rule of thumb: quantities and capacity decisions almost always strategic substitutes, whereas prices almost always strategic complements.

So what?

So what?

These concepts tell us something about how a firm expects its rivals to react to its tactical manoeuvres:

- when actions are strategic complements, increased aggression will elicit increased aggression in the rival:

e.g. prices: a competitor's price cut (an aggressive move) will best be responded to by a price cut (also an aggressive move), since the reaction functions are upwards sloping.

- when actions are strategic substitutes, increased aggression will result in lessened aggression in the rival:

e.g. quantities: a competitor's quantity increase (aggressive) will best be responded to by a quantity cut (a soft response), since the reaction functions are downwards sloping.

(See Besanko et al. Chapter 8: Strategic Commitment and Competition).

Compare the Cournot and Bertrand duopoly profits in the benchmarking below.

1.17 Benchmarking Oligopoly Behaviour

Two companies produce homogeneous output.

Linear industry demand curve of $P = 10 - Q$,
where Q is the sum of the two companies' outputs, $Q = y_1 + y_2$.

Both companies have identical costs, $AC = MC = \$1/\text{unit}$.

There are five possibilities for the equilibrium levels of prices, outputs, and profits.

1. Competitive Price Taking
2. Monopolistic Cartel
3. Cournot Oligopolists
4. von Stackelberg Quantity Leadership
5. Bertrand Simultaneous Price Setting.

1.17.1 Competitive Price Taking

Each setting price equal to marginal cost.

So: Price $P_{PC} = \$1/\text{unit}$,
the total quantity $Q = 9$ units between them,
and each produces output $y_1 = y_2 = 4.5$ units.

Since $P_{PC} = AC$, their profits are zero: $\pi_1 = \pi_2 = 0$.

1.17.2 Monopolistic Cartel

Collude and act as a monopolistic *cartel*.

Each produces half of the monopolist's output and receives half the monopolist's profit.

Output Q_M such that $MR(Q_M) = MC = \$1/\text{unit}$.

The MR curve is given by $MR = 10 - 2Q$, which results in

$$Q_M = 4.5 \text{ units,}$$

$$P_M = \$5.5/\text{unit, and}$$

$$\pi_M = (5.5 - 1) \times 4.5 = \$20.25.$$

Each produces output $y_1 = y_2 = 2.25$ units, and earns $\pi_1 = \pi_2 = \$10.125$ profit.

1.17.3 Cournot Oligopolists

Cournot oligopolists, each choosing an amount of output to maximise its profit, each assuming that the other is doing likewise: not colluding, but competing. They choose simultaneously.

Cournot equilibrium occurs where their *reaction curves* intersect and the expectations of each of what the other is doing are fulfilled.

Firm 1 determines Firm 2's reaction function: "If I were Firm 2, I'd choose my output y_2^* to maximise my Firm 2 profit conditional on the expectation that Firm 1 produced output of y_1^e ."

$$\max_{y_2} \pi_2 = (10 - y_2 - y_1^e) \times y_2 - y_2$$

Thus $y_2 = \frac{1}{2} (9 - y_1^e)$, which is Firm 2's reaction function, given its conjecture y_1^e of Firm 1's behaviour.

Since the two firms are identical, Cournot equilibrium occurs where the two reaction curves intersect, at $y_1^* = y_1^e = y_2^* = y_2^e = 3$ units.

So $Q_{C0} = 6$ units, price P_{C0} is then \$4/unit, and the profit of each firm is \$9.

1.17.4 von Stackelberg Quantity Leadership

What if one firm, Firm 1, gets to choose its output level y_1 first?

It realises that Firm 2 will know what Firm 1's output level is when Firm 2 chooses its level: this is given by Firm 2's reaction function from above, but with the actual, not the expected, level of Firm 1's output, y_1 .

So Firm 1's problem is to choose y_1^* to maximise its profit:

$$\max_{y_1} \pi_1 = (10 - y_2 - y_1) \times y_1 - y_1,$$

where Firm 2's output y_2 is given by Firm 2's reaction function: $y_2 = \frac{1}{2}(9 - y_1)$.

Substituting this into Firm 1's maximisation problem:

$y_1^* = 4.5$ units, and so $y_2^* = 2.25$ units, so that $Q_{St} = 6.75$ units and $P_{St} = \$3.25/\text{unit}$.

Profits are $\pi_1 = \$10.125$ (the same as in the cartel case above) and $\pi_2 = \$5.063$ (half the cartel profit).

1.17.5 Bertrand Simultaneous Price Setting.

Remember: Equilibrium means there is no incentive for either firm to undercut the other.

The only equilibrium when they compete using price is where each is selling at $P_1 = P_2 = MC_1 = MC_2 = \$1/\text{unit}$.

Identical to the price-taking case above.

Note: Were MC_1 greater than MC_2 , then Firm 2 would capture the whole market at a price just below MC_1 , and would make a positive profit; and $y_1 = 0$.

	Output	Profit	Output	Profit	Price	Quantity
	y_1	π_1	y_2	π_2	P	Q
Price-taking	4.5	0	4.5	0	1	9
Cartel	2.25	10.125	2.25	10.125	5.5	4.5
Cournot	3	9	3	9	4	6
von Stackelberg	4.5	10.125	2.25	5.063	3.25	6.75
Bertrand	4.5	0	4.5	0	1	9

Summary of Outcomes.
